## Disclaimer

74
Findings are generally nonspecific and secondary to primary infection. They include malaise, leukocytosis, tachypnea, and pulse >90 bpm.

Sepsis can progress rapidly to multiorgan failure and shock, and is often fatal. Survival is dependent on a high index of suspicion of sepsis, early recognition, and immediate intervention.

Patients with evidence of sepsis, including signs of organ dysfunction, require immediate hospital assessment.

Empiric broad-spectrum antibiotic therapy (based on the most probable pathogens) should be administered as soon as possible, and always within the first hour following recognition.

Blood cultures, as well as cultures of all wounds or other potentially infected body fluids, should be performed as indicated by symptoms and the risk profile of the patient, ideally before the initiation of antimicrobial treatment.

Any source of infection should be controlled as a matter of urgency, preferably within 6 hours following recognition.

Evidence of hypoperfusion or shock should be identified and treated with immediate intravenous fluid challenges, if present. Shock that fails to respond to fluid challenges necessitates urgent critical care referral for consideration of vasopressors and/or inotropes.
Definition

Sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to an infection.[1] The definition of sepsis was updated in 2016 following publication of the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3).[1]

The 2016 consensus definitions also recommend that the Sequential (Sepsis-related) Organ Failure Assessment (SOFA) criteria and “quick” (q)SOFA criteria be used to identify sepsis, in place of the currently used systemic inflammatory response syndrome (SIRS) criteria, which were the basis for the previous definition of sepsis.[1] [2] SOFA is an ICU-based mortality score and qSOFA is a rapid, shortened version of SOFA designed for use outside the ICU. The SOFA scores are not in themselves clinical predictors of sepsis, and they rely on clinical suspicion for the scores to be assessed. Furthermore, qSOFA has not been prospectively validated, and its place in clinical practice has not been fully established. Although the SIRS criteria are no longer recommended and have limitations, they are well established after many years of use.[3] At present it is unclear which clinical score will best guide sepsis care; therefore, the SIRS criteria remain the current standard for identifying sepsis and are likely to remain relevant in medical care, at least in the short term.

SIRS is a multisystem response that can result from infection (localized or general), as well as from noninfectious causes (e.g., trauma, burns, or pancreatitis).[4] [5] [6] [7] [8] It is defined by the presence of 2 or more criteria from the following: temperature >101 °F (38.3 °C) or <96.8 °F (36.0 °C); tachycardia >90 bpm; tachypnea >20 breaths/minute or PaCO2 <32 mmHg; hyperglycemia (blood glucose >140 mg/dL [>7.7 mmol/L]) in the absence of diabetes mellitus; acutely altered mental status; leukocytosis (WBC count >12,000/microliter); leukopenia (WBC count <4000/microliter); or a normal WBC count with >10% immature forms.[5] [Surviving Sepsis Campaign: evaluation for severe sepsis screening tool]

When using the SIRS criteria, sepsis is the presence of SIRS (i.e., 2 or more SIRS criteria) resulting specifically from an infection.

In the first international consensus definitions, which date from 1991, severe sepsis was defined as sepsis associated with organ dysfunction, hypoperfusion, or hypotension; septic shock was defined as sepsis with hypotension despite adequate fluid replacement.[5] These definitions remain clinically established in many clinical settings.

However, the 2016 third international consensus (Sepsis-3) definitions state that the term “severe sepsis” should be made redundant in light of the revisions to the definition of sepsis.[1] Septic shock has also been redefined as a subset of sepsis in which profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone.[1]

In 2016, the UK National Institute for Health and Care Excellence (NICE) published guidance on the recognition, diagnosis, and early management of sepsis, which highlighted that the Sepsis-3 international consensus definitions of sepsis have limited use in the early identification of people at risk of sepsis.[9] The NICE guidelines propose a move away from using the SIRS criteria, and do not immediately support the use of the SOFA/qSOFA criteria. Instead NICE proposes a risk stratification approach to categorize patients into 3 groups according to their risk of severe illness or death from sepsis: high risk; moderate to high risk; or low risk. The risk stratification is based on the patient’s: history (e.g., altered mental state; urine output; impaired immunity; or recent trauma, surgery, or invasive procedure), appearance (e.g., signs of potential infection; mottled or ashen appearance; cyanosis of skin, lips, or tongue; or nonblanching rash of skin), and clinical
Sepsis in adults

**Basics**

evaluation (e.g., temperature, heart rate, respiratory rate, blood pressure, level of consciousness, and oxygen saturation).

**Epidemiology**

In 2007, septicemia was recorded as the 10th leading cause of death in the US.[11] There are as many as 750,000 to 900,000 cases per year, resulting in around 200,000 deaths per year.[12] Most epidemiologic studies find sepsis to be more common in men than in women. Patients older than 65 years of age are particularly susceptible, with one study finding almost two-thirds of cases to be in people over 65.[13] This study recorded 215,000 sepsis-associated deaths (9.3% of all deaths in the US during the study period).

The population-based incidence of sepsis is estimated to be as high as 176 to 380 cases per 100,000 per year.[14] [15] [16] [17] However, incidence rates depend on the definition of sepsis, with rates in Canada cited as 15.7 cases per 100,000 population per year requiring admission to ICU.[18] Nonetheless, it is likely that there are as many as 30.5 million cases of sepsis annually worldwide, with an estimated 5.3 million deaths annually. [19] The incidence of sepsis is also likely to be rising.

**Etiology**

Causative agents vary significantly depending on the region, hospital size, season, and type of unit (neonatal, transplantation, oncology, or hemodialysis units).[20] [21] [22] [23] [24] [25] [26] [27] [28] [29]

It should be noted that pathogenic organisms are identified in only around half of cases of sepsis.[30] Where organisms are identified, bacteria (gram-positive and gram-negative) are identified as the causative organism in approximately 90% of cases, with gram-positive bacteria and fungal infections increasing in frequency.[31] Since the mid-1980s, the frequency of gram-positive sepsis (mainly caused by *Staphylococcus aureus*, coagulase-negative staphylococci, enterococci, and streptococci) has surpassed that of gram-negative sepsis (mainly caused by Enterobacteriaceae, especially *Escherichia coli* and *Klebsiella pneumoniae*, and by *Pseudomonas aeruginosa*). However, *E coli* remains the most prevalent pathogen causing sepsis.[4] [18] [20] [32] [33] Some experts believe that the host response to some viral infections so closely mimics sepsis that it should be considered as such.

In the majority of cases of sepsis arising in the community, the causative organisms will be sensitive, frequently endogenous bacteria. In the UK, a report of the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) study in sepsis published in November 2015 highlighted that nearly 75% of cases of sepsis arose as a result of community-acquired infection.[30] However, it should be acknowledged that resistance patterns of organisms continue to change and can differ greatly according to region. For example, in one large multicenter European study, >50% of isolates in ICU were methicillin-resistant *S aureus* (MRSA).[34] Over the last two decades, vancomycin-resistant enterococci (VREs) have emerged, with >10% of enterococci being VREs.[35] Just as concerning is the significant number of *E coli* isolates that are now resistant to amoxicillin/clavulanic acid (around 40%).[36] MRSA is increasingly prevalent in the community, with community-acquired MRSA presenting as a severe pneumonia, often with cavitation, in patients with a recent coryzal illness. In the UK, sepsis is the most common direct cause of maternal death, ahead of venous thromboembolism.[37] Following pregnancy (in the 6-week postpartum period), group A streptococci are the most common causative agent.[38]

Studies tend to broadly concur on the relative frequencies of sources of infection.[10] [34] In the SOAP study, the respiratory tract accounted for 60%; the bloodstream 20%; abdomen 26%; skin 14%; and urinary system...
12%. The Surviving Sepsis Campaign observational study of over 15,000 patients showed slightly fewer patients with respiratory sources (44.4%), and a greater frequency of urosepsis (20.8%). However, in 20% to 30% of patients, a definite source of infection is not found.

The leading fungal pathogen causing sepsis has been identified as *Candida*. In a European point-prevalence study, fungi were isolated from 17% of ICU patients with nosocomial infection. Fungi are more prevalent as isolates in patients with secondary or tertiary peritonitis, with *Candida* identified in up to 20% of patients with GI tract perforation. Risk factors include fecal soiling of the peritoneum, recurrent GI perforation, immunosuppressive therapy for neoplasm or in post-transplant patients, and the presence of inflammatory diseases. These patients carry a high risk of mortality.

**Pathophysiology**

Sepsis is a syndrome comprising an immune system-mediated collection of physiologic responses to an infectious agent. Clinical signs such as fever, tachycardia, and hypotension are common but the clinical course depends on the type and resistance profile of the infectious organism, the site and size of the infecting insult, and the genetically determined or acquired properties of the host’s immune system.

Immune-system activation:

- Pathogen entry and survival is facilitated by tissue contamination (surgery or infection), foreign body insertion (catheters), and immune status (immunosuppression).
- The innate immune system is activated by bacterial cell wall products, such as lipopolysaccharide, binding to host receptors, including Toll-like receptors (TLRs). These are widely found on leukocytes and macrophages, and some types are found on endothelial cells. At least 10 TLRs have been described in humans. These have specificity for different bacterial, fungal, or viral products, and genetic polymorphisms are associated with a predisposition to shock with gram-negative organisms.
- Activation of the innate immune system results in a complex series of cellular and humoral responses, each with amplification steps:
  - Pro-inflammatory cytokines, such as tumor necrosis factor (TNF)-alpha and interleukins 1 and 6 are released, which in turn activate immune cells.
  - Reactive oxygen species, nitric oxide (NO), proteases, and pore-forming molecules are released, which bring about bacterial killing. NO is responsible for vasodilatation and increased capillary permeability, and has been implicated in sepsis-induced mitochondrial dysfunction.
  - The complement system is activated, and mediates activation of leukocytes, attracting them to the site of infection where they can directly attack the organism (phagocytes, cytotoxic T lymphocytes), identify it for attack by others (antigen-presenting cells, B lymphocytes), “remember” it in case of future infection (memory cells, B lymphocytes), and cause the increased production and chemotaxis of more T helper cells.

The endothelium and coagulation system:

- The vascular endothelium plays a major role in the host’s defense to an invading organism, but also in the development of sepsis. Activated endothelium not only allows the adhesion and migration of stimulated immune cells, but becomes porous to large molecules such as proteins, resulting in the tissue edema.
Sepsis in adults

BASICS

• Alterations in the coagulation systems include an increase in procoagulant factors, such as plasminogen activator inhibitor type I and tissue factor, and reduced circulating levels of natural anticoagulants, including antithrombin III and activated protein C (APC), which also carry anti-inflammatory and modulatory roles.[49] [50]

Inflammation and organ dysfunction:

• Through vasodilatation (causing reduced systemic vascular resistance) and increased capillary permeability (causing extravasation of plasma), sepsis results in relative and absolute reductions in circulating volume.

• A number of factors combine to produce multiple organ dysfunctions. Relative and absolute hypovolemia are compounded by reduced left ventricular contractility to produce hypotension. Initially, through an increased heart rate, cardiac output increases to compensate and maintain perfusion pressures, but as this compensatory mechanism becomes exhausted, hypoperfusion, and shock may result.

• Impaired tissue oxygen delivery is exacerbated by pericapillary edema. This means that oxygen has to diffuse a greater distance to reach target cells. There is a reduction of capillary diameter due to mural edema and the procoagulant state results in capillary microthrombus formation.

• Additional contributing factors include disordered blood flow through capillary beds, resulting from a combination of shunting of blood through collateral channels and an increase in blood viscosity secondary to loss of red cell flexibility.[51] As a result, organs may become hypoxic, even though gross blood flow to an organ may increase. These abnormalities may lead to lactic acidosis, cellular dysfunction, and multiorgan failure.[52]

• Cellular energy levels fall as metabolic activity begins to exceed production. However, cell death appears to be uncommon in sepsis, implying that cells shut down as part of the systemic response. This could explain why relatively few histologic changes are found at autopsy, and the eventual rapid resolution of severe symptoms, such as complete anuria and hypotension, once the systemic inflammation resolves.[53]

Classification

Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) (2016)[1]

• Sepsis has been redefined as life-threatening organ dysfunction caused by a dysregulated host response to an infection.

• Owing to revisions to the definition of sepsis, the term “severe sepsis” (as previously defined in the 1991/2001 international consensus definitions) should be made redundant.

• Septic shock has also been redefined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. Septic shock can be defined clinically as a patient diagnosed with sepsis, with persistent hypotension requiring vasopressors to maintain a mean arterial pressure (MAP) ≥ 65 mmHg, and a lactate level > 18 mg/dL (>2 mmol/L), despite adequate fluid resuscitation.
In the 1991 definitions (which were reviewed in 2001) sepsis is defined as a systemic inflammatory response to a new infection, and severe sepsis is defined as sepsis associated with organ dysfunction, hypoperfusion, or hypotension.

Sepsis with hypoperfusion is defined by the presence of acute circulatory failure, characterized by arterial hypotension (systolic BP <90 mmHg, reduced by > 40 mmHg from baseline or mean arterial pressure [MAP] of <65 mmHg), or other evidence of hypoperfusion, such as serum lactate > 18 mg/dL (>2 mmol/L).

Septic shock is defined as being present when hypoperfusion persists for at least 1 hour despite adequate fluid resuscitation and is unexplained by other causes. However, hypoperfusion is in itself a clinical emergency and should be corrected as soon as is practicable. The distinction between hypoperfusion and shock in this context is theoretical; in reality the urgency is identical.

Although the 1991 definitions have been superseded by the 2016 Sepsis-3 definitions, these changes have prompted much debate and the 1991 definitions remain in widespread clinical use while the controversies are resolved.

Sepsis: recognition, diagnosis and early management (National Institute for Health and Care Excellence, 2016)

In 2016, the UK National Institute for Health and Care Excellence (NICE) published guidelines on sepsis recommending that patients with suspected sepsis should be stratified according to risk of severe illness or death from sepsis (i.e., low risk, moderate to high risk, and high risk).
**Case history**

**Case history #1**

A 78-year-old woman presents to the hospital for an elective right hemicolecotmy. She has a past medical history of hypertension, angina on exertion, and diabetes mellitus. She is independently mobile, does her own shopping, and has a 30-pack-a-year history of smoking. The operation was uncomplicated. On day 5 post-surgery, she becomes confused. On examination, she has a Glasgow Coma Scale score of 14/15. She has a temperature of 101.3°F (38.5°C), a respiratory rate of 28 breaths/minute, and oxygen saturations of 92% on 2 L of oxygen. She is tachycardic at 118 bpm, and her BP is 110/65 mmHg. On chest auscultation, she has coarse crackles in the right lower chest. Her surgical wound appears to be healing well and her abdomen is soft and not tender.

**Other presentations**

Sepsis may complicate benign primary infections found in any age group and requires a high suspicion for the clinical signs of systemic inflammatory response (tachycardia, fever, tachypnea, or respiratory compromise).

Altered mental status may also be a presenting feature, especially in older patients. Mild disorientation or confusion is common with more severe presentations, including significant anxiety, agitation, and loss of consciousness.

Other features that may be present include reduced urine output; a mottled or ashen appearance; cyanosis of skin, lips, or tongue; or presence of a nonblanching rash on the skin.[9]

**Step-by-step diagnostic approach**

Sepsis is a spectrum of disease, where there is a systemic and dysregulated host response to an infection.[1] Presentation may range from nonspecific or nonlocalized symptoms (e.g., feeling ill with a normal temperature), to severe signs with evidence of multiorgan dysfunction and septic shock. Risk of progression to fulminant disease is determined by various factors, including:

- Magnitude and nature of the infective focus
- Timing and quality of interventions
- Genetic and acquired predisposition of the patient.

Early recognition and diagnosis is essential because early treatment is associated with significant short- and long-term benefits in outcome.[56] [57] [58] [59] [60] [9]

**Diagnostic criteria**

There is ongoing debate about the most appropriate criteria for diagnosing sepsis in clinical practice, with several different approaches suggested. These include use of the systemic inflammatory response syndrome (SIRS) criteria in the presence of infection; the Sequential (or sepsis-related) Organ Failure Assessment (SOFA) score recommended by the Sepsis-3 international consensus group; and use of a risk stratification system as recommended by guideline groups in the US and UK.
In practice, sepsis is usually diagnosed by the clinical identification of an infection in a patient who meets the clinical criteria for SIRS. According to the international consensus definition published in 1991 (and reviewed in 2001), SIRS is defined by the presence of 2 or more criteria from a collection of clinical signs and laboratory investigations as follows. (Hyperglycemia and acutely altered mental status are not part of the original criteria for SIRS, but have since been included by the Surviving Sepsis Campaign in their screening tool.)[5] [Surviving Sepsis Campaign: evaluation for severe sepsis screening tool]

- Temperature>101°F (38.3°C) or <96.8°F (36.0°C)
- Tachycardia> 90 bpm
- Tachypnea>20 breaths/minute or PaCO2 <32 mmHg
- Leukocytosis (WBC count> 12,000/microliter)
- Leukopenia (WBC count <4000/microliter)
- Normal WBC count with> 10% immature forms.
- Hyperglycemia (blood glucose> 140 mg/dL [>7.7 mmol/L]) in the absence of diabetes mellitus
- Acutely altered mental status.

In 2016, the definition of sepsis was updated by the Third International Consensus Group (Sepsis-3) to reflect greater understanding of the disease. This step was taken because the SIRS criteria were found to be too non-specific to be useful in defining sepsis: they defined sepsis as life-threatening organ dysfunction caused by a dysregulated host response to an infection. Rather than using the SIRS criteria to identify these patients (upon which the previous definition was based), the Sepsis-3 advised that sepsis should be defined using the SOFA criteria.[1] The SOFA score is calculated based on the assessment of the following systems (with a score of ≥2 in a patient with a suspected infection being suggestive of sepsis):[1]

![SOFA Score Table](https://example.com/sboa-score-table.png)

**Sequential (or Sepsis-related) Organ Failure Assessment (SOFA) criteria**
As the SOFA score has primarily been validated on patients in an ICU setting and requires multiple laboratory test results, the Third International Consensus Group suggested the use of the “quick SOFA” (qSOFA) as a bedside assessment to identify those at risk of deterioration due to sepsis. This is a simple clinical assessment that assesses for the presence of at least two of the following:[1]

- Altered mental state
- Systolic blood pressure ≤100 mmHg
- Respiratory rate ≥ 22 breaths/minute.

However, since the introduction of qSOFA, a large study in the US found it had poor sensitivity (particularly when compared with other bedside early warning scores and the SIRS criteria) and was a late indicator of deterioration.[61]

Further studies will be needed to determine the optimal screening methods for early recognition of sepsis.

The 2016 Sepsis-3 definitions also recommend that the term "severe sepsis", as previously defined, should be made redundant in light of revisions to the definition of sepsis.[1] Septic shock has also been redefined as a subset of sepsis in which profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone.[1] According to the 2016 international consensus definition, septic shock should be defined as sepsis with both of the following (despite adequate volume resuscitation):[1]

- Persistent hypotension requiring vaspressors to maintain mean MAP ≥65 mmHg, and
- Serum lactate > 18 mg/dL (>2 mmol/L).

Patients with septic shock (as defined by the Sepsis-3) are associated with hospital mortality rates greater than 40%.[1]

In 2016, the UK National Institute for Health and Care Excellence (NICE) published guidelines which focus on the early recognition and identification of sepsis.[9] In a move away from the SIRS and SOFA criteria recommended by the international consensus definitions, the NICE guidelines recommend a risk stratification approach to identify early those patients at highest risk. The approach involves categorizing a patient as being at low risk, moderate to high risk, or high risk of severe illness or death from sepsis, based on the following criteria:

- History (altered behavior; altered mental state; functional ability; impaired immunity; or recent trauma, surgery, or invasive procedure)
- Respiratory (respiratory rate; new need for oxygen to maintain saturation)
- Systolic blood pressure
- Circulation and hydration (raised heart rate; urine output)
- Skin (signs of infection; mottled or ashen appearance; cyanosis of skin, lips, or tongue; nonblanching rash of skin).

This focus on early identification of patients at risk of sepsis is shared with the American College of Emergency Physicians (ACEP) Expert Panel on Sepsis in their tool DART (Detect, Act, Reassess, Titrate).[62] The NICE guidelines also provide further recommendations for in-hospital clinical assessment and laboratory investigations (e.g., venous blood test for blood gas, including glucose and lactate...
measurement; blood culture; CBC; CRP; BUN and serum electrolytes; creatinine; and coagulation) in patients with suspected sepsis based on their risk profile and symptoms.[9]

There are multiple scoring systems and definitions for sepsis and sepsis with organ dysfunction. None is perfect and many seek to measure similar variables. Furthermore, the NICE sepsis guidelines published in the UK have highlighted a limitation of the international consensus definitions in that they are unproven in the early identification of people at risk of sepsis.[9] At present, SIRS and the earlier international consensus definitions of sepsis, severe sepsis, and septic shock remain clinically established in most clinical settings.

**Initial evaluation**

Sepsis may present initially with nonspecific, nonlocalized symptoms, such as feeling ill with normal temperature. Sepsis should be considered if a patient presents with signs or symptoms that indicate possible infection, regardless of temperature.[9] This is because, although fever is frequently associated with sepsis, hypothermia is a common presenting sign and carries a worse prognosis. [63] Initial assessment includes identifying the likely source of infection, identifying risk factors for sepsis, determining the need for urgent source control (e.g., incision and drainage of an abscess), and identifying abnormalities of behavior, circulation, or respiration.

As for all acutely ill patients, initial evaluation should follow the ABCDE format, to include assessment of the airway, respiratory, and circulatory sufficiency, and conscious level (Glasgow Coma Scale or AVPU [Alert, responds to Voice, responds to Pain, Unresponsive]). Attention should be paid to seeking other signs of organ dysfunction (jaundice, purpura fulminans, cyanosis), and signs of circulatory insufficiency including oliguria, mottling of the skin, and prolonged capillary refill times. Oxygen saturation, respiratory rate, heart rate, BP, temperature, and accurate hourly fluid balance (including urine output) should be monitored. It is important to seek clinical evidence for the source of infection. This will aid diagnosis and provide vital information as to the patient’s risk factors for sepsis. Risk factors strongly associated with sepsis include: underlying malignancy, impaired immunity (e.g., due to illness or drugs), recent surgery or other invasive procedures, breached skin integrity (e.g., wounds, skin infection), indwelling catheter, intravenous drug misuse, age >65 years or frailness, pregnancy or recent pregnancy, hemodialysis, hx of alcoholism, immunocompromise, and diabetes mellitus.

[Sfig-2]

[Sfig-3]

Sepsis is typically diagnosed when there are alterations in conscious level, hypotension, and organ failure, manifesting as oliguria, hypoxemia, jaundice, or petechial rash. However, delayed diagnosis and intervention are associated with increased morbidity, and a high index of suspicion in all patients with abnormal signs and a possibility of infection should be maintained.

**Investigations**

Initial investigations cover 4 purposes:

- To identify causative organisms
- To evaluate for organ dysfunction
- To identify the source of infection
- To prognosticate, to aid in the selection of an appropriate level of care.
Sepsis in adults

Diagnosis

Priority should be given to those investigations that will help to answer important clinical questions, such as the source of infection and severity of illness. Cultures of blood and other fluids will take 48 to 72 hours to yield sensitivities of causative organisms (if identified), but are far less sensitive if delayed until after antimicrobial administration.

Investigations to identify causative organisms:

- Blood cultures should be taken immediately, and preferably before antibiotics are started, provided their sampling will not delay administration of antibiotics. Ideally, at least one set should be taken percutaneously, and one set from any vascular access device that has been in situ for more than 24 hours. Other cultures (e.g., of sputum, cerebrospinal fluid (CSF), pleural fluid, joint fluid, stool, and urine) should be taken as clinically indicated.
- If no localizing signs are present, examination and culture of all potential sites of infection, including wounds, catheters, prosthetic implants, epidural sites, and pleural or peritoneal fluid, as indicated by the clinical presentation and history, is required.
- If meningitis is suspected (e.g., headache, photophobia, neck stiffness, vomiting), a lumbar puncture (LP) for CSF microscopy and culture should be performed. A CT scan prior to performing an LP to exclude elevated intracranial pressure is required if there is any clinical suspicion of this.

[VIDEO: Diagnostic lumbar puncture in adults: animated demonstration]

- If an enclosed collection such as an abscess or empyema is suspected, it is recommended that this be drained and cultured early in the course of the illness (within 6 hours following identification).
- Intubated patients in whom there is a suspicion of pneumonia should have tracheal aspirates, broncho-alveolar lavage, or protected brush specimens taken.

Evaluation for organ dysfunction:

- Baseline assessment of liver function tests (notably bilirubin), a CBC (with differential), coagulation (INR, PTT), serum creatinine, and BUN.
- Serum electrolytes and glucose are frequently deranged, and should be measured at baseline and regularly until the patient improves.
- Elevated serum lactate highlights tissue hypoperfusion, and is most reliably assessed using an arterial blood gas (ABG) sample. However, in practice, a venous blood gas (VBG) sample is generally used, as it is generally easier and quicker to obtain compared with ABG. Most patients do not undergo ABG sampling unless there is respiratory compromise.
- Markers of inflammation, including CRP and procalcitonin, are of use in determining clinical progress and response to therapy. Serial measures of procalcitonin can be useful as a guide to the need to continue or stop empiric antibiotics. However, evidence for the prognostic value of procalcitonin is unclear, and the use of procalcitonin in the identification of sepsis is excluded from many guidelines.

Investigations to identify the source of the infection:

- The source of infection may be immediately evident; for example, with classical signs and symptoms of pneumonia (purulent sputum, dyspnea, tachypnea, cyanosis) or peritonism (abdominal pain, guarding, distension, tenderness, absent bowel sounds). However, in many patients the origin must be actively sought.
• Diagnostic studies may identify a source of infection that requires removal of a foreign body or drainage to maximize the likelihood of a satisfactory response to therapy. Chest x-rays and ultrasound scans can be performed at the bedside. Examinations such as CT scanning require transfer of potentially unstable patients and the benefit should be weighed against the risk.
• In patients at risk of, or with symptoms compatible with, bacterial endocarditis, a transthoracic or transesophageal echocardiogram is useful. This is also helpful to differentiate between hypovolemic, cardiac, and septic shock, as well as alternative diagnoses, such as valvular abnormalities, pulmonary embolus, myocardial ischemia (with segmental or global dysfunction), hypovolemia, and pulmonary hypertension. If readily available, an echocardiogram may also be appropriate in patients with sepsis of unknown origin.
• An ECG should be arranged to help exclude other differential diagnoses, including MI, pericarditis, and myocarditis. Sepsis also predisposes to myocardial dysfunction (particularly in septic shock)\[76\] and arrhythmias (e.g., atrial fibrillation).\[9\]

Certain investigations carry prognostic value and can help determine the need for critical care:

• Lactate measurement is a useful assessment of perfusion once a diagnosis of sepsis has been established. Increasing levels of lactate are associated with increasing levels of anaerobic metabolism. Persistently elevated lactate levels may parallel the degree of hypoperfusion or organ failure. High lactate carries adverse prognostic value if elevated to $>18$ mg/dL ($>2$ mmol/L), and still worse outcomes are associated with levels $>36$ mg/dL ($>4$ mmol/L).\[9\] Lactate clearance (the rate at which lactate is cleared over a period of 6 hours) has been demonstrated to be as useful as more invasive tests, such as central venous oxygen saturation, in determining a patient’s response to treatment.\[77\] \[78\]
• Studies with trauma patients have evaluated lactate levels against Acute Physiology and Chronic Health Evaluation (APACHE) scores and lactate clearance rates and found lactate levels to be inferior in informing the prognosis. However, an APACHE score takes 24 hours to calculate.\[79\]
• An alternative measure is serum procalcitonin levels. In patients with acute respiratory infections (including those with sepsis), procalcitonin guided antibiotic therapy has been shown to reduce the antibiotic course length, reduce antibiotic related complications and reduce the 30 day mortality rate.\[80\] However, evidence for the prognostic value of procalcitonin alone is unclear,\[81\] and the use of procalcitonin in the identification of sepsis is excluded from many guidelines. Changes in procalcitonin levels may occur later than that of lactate, although changes in both markers combined are highly predictive of outcome between 24 and 48 hours.\[82\]
• Some experts recommend the use of shock index (heart rate divided by systolic BP) as a predictor of requirement for critical care, with one group finding an index of $>0.9$ to be predictive.\[83\]
• More recently, noninvasive impedance echocardiography has been shown, if a cardiac index of $<2$ is identified, to predict poor outcome.\[84\]

Patients suffering from septic shock who have not responded to initial fluid resuscitation will require invasive monitoring and treatment in high dependency units.

**Emerging tests**

The PhenoTest™ BC Kit can identify 14 species of bacteria and 2 species of yeast that commonly cause bloodstream infections, while also providing guidance on antibiotic sensitivity. The test compares the
organism’s DNA to a database, and then uses time-lapse images to analyze the organism’s response to antibiotics. It can identify a positive blood culture in 1.5 hours and guide antibiotic treatment in 6.5 hours. However, the test has been associated with false positive results.[85]

A number of other rapid detection methods for early pathogen detection and antimicrobial susceptibility testing are in clinical testing at present. Such assays could be of significant value in the personalized care of septic patients in the near future.

Risk factors

**Strong**

**underlying malignancy**
- Incidence rates of sepsis are up to 995 cases per 100,000 per year in patients with malignancy. Immunosuppression (including both the severity and duration of neutropenia where present), recurrent infections, invasive catheterizations, and treatment of resistant organisms contribute to the increased risk (odds ratio [OR] 9.77, 95% confidence interval [CI] 9.67 to 9.88).[33]

**age >65 years**
- Associated with an increased risk of sepsis (relative risk [RR] 7.0, 95% CI 5.6 to 8.7).[18]
- Risk of sepsis is particularly high in people ages >75 years or those who are frail.[9]

**immunocompromise**
- Associated with an increased risk of sepsis.
- Immunocompromise may arise from treatment (e.g., chemotherapy, corticosteroids, or other immunosuppressants), underlying disease (e.g., diabetes, sickle cell), or surgery (e.g., splenectomy).[9] [54]

**hemodialysis**
- Associated with an increased risk of sepsis (RR 208.7, 95% CI 142.9 to 296.3).[18]

**alcoholism**
- Associated with an increased risk of sepsis (RR 5.6, 95% CI 3.8 to 8.0).[18]

**diabetes mellitus**
- Decreased resistance to infections, complications of diabetes, and increased surgical complications play a role (RR 5.9, 95% CI 4.4 to 7.8).[18]

**recent surgery or other invasive procedures**
- Risk of sepsis is high in people who have had surgery or other invasive procedures in the past 6 weeks.[9]
- Risk of sepsis is particularly high following esophageal, pancreatic, or elective gastric surgery.[55]

**breached skin integrity**
- Risk of sepsis is high in people with any breach of skin integrity (e.g., cuts, burns, blisters, or skin infection).[9]
indwelling lines or catheters
• Risk of sepsis is high in people with indwelling lines or catheters.[9]

intravenous drug misuse
• Risk of sepsis is high in people who misuse drugs intravenously.[9]

pregnancy
• Pregnancy or recent pregnancy is a risk factor for the development of sepsis.[9]
• Risk of sepsis among women may be higher if they have impaired immunity, gestational diabetes, diabetes (or other comorbid condition), needed invasive procedures during pregnancy (e.g., cesarean section, forceps delivery, removal of retained products of conception), had prolonged rupture of membranes during pregnancy, have or have been in close contact with people with group A streptococcal infection (e.g., scarlet fever), or have continued vaginal bleeding or an abnormal vaginal discharge with odor.[9]

Weak
urban residence
• May predispose to increased exposure to infections and drug-resistant pathogens (RR 2.4, 95% CI 1.2 to 5.6).[18]

lung disease
• Weakly associated with sepsis (RR 3.8, 95% CI 2.6 to 5.4).[18]

male gender
• May be at greater risk (OR 1.28, 95% CI 1.24 to 1.32).[14]

non-white ancestry
• May be at increased risk (OR 1.90, 95% CI 1.80 to 2.00).[14]

winter season
• Seasonal infections (e.g., respiratory infections in winter) are weakly associated with sepsis.
• Sepsis is 1.4 times more likely to occur in the winter than in the fall.[26]

History & examination factors

Key diagnostic factors

high (>101°F [>38°C]) or low (<96.8°F [<36°C]) temperature (common)
• Temperature should not be used as the sole predictor of sepsis and should not be used to rule sepsis either in or out.
• Fever may not be apparent in the following groups of people with sepsis: older people or those who are very frail, people undergoing treatment for cancer, immunocompromised people, and severely ill people with sepsis.
• Temperature rise can result from a physiologic response (e.g., after surgery or trauma).

tachycardia (common)
Sepsis in adults

**Diagnosis**

- Heart rate >90 bpm (>100 bpm in pregnant women).

**Tachypnea (common)**
- Respiratory rate >20 breaths/minute.

**Acutely altered mental status (common)**
- Due to impaired cerebral perfusion and inflammatory cytokines.

**Poor capillary refill, mottling of the skin, or ashen appearance (common)**
- Signs of circulatory insufficiency.

**Signs associated with specific source of infection (common)**
- The source of infection may be immediately evident; for example, with classical signs and symptoms of pneumonia (purulent sputum, dyspnea, tachypnea, cyanosis) or peritonism (abdominal pain, guarding, distension, tenderness, absent bowel sounds). However, in many patients the origin must be actively sought.

**Low oxygen saturation (common)**
- Sign of circulatory insufficiency.

**Arterial hypotension (common)**
- Systolic BP <90 mmHg, mean arterial pressure (MAP) <65 mmHg, or reduction in systolic BP >40 mmHg from baseline.
- May be present when sepsis leads to organ dysfunction.
- The use of vasopressor agents to correct hypotension does not exclude shock.

**Decreased urine output (common)**
- Urine output <0.5 mL/kg/hour for at least 2 hours, or no urine passed in the last 18 hours.
- May be present when sepsis leads to organ dysfunction.

**Cyanosis (common)**
- Sign of circulatory insufficiency.

**Other diagnostic factors**

**Purpura fulminans (common)**
- Sign of organ dysfunction.

**Jaundice (uncommon)**
- Sign of organ dysfunction.

**Ileus (uncommon)**
- May be present when sepsis leads to organ dysfunction.
### Diagnostic tests

| **lactate levels**                             | *Elevated serum lactate highlights tissue hypoperfusion, and is most reliably assessed using an ABG sample.*[73]  
*Increasing levels of lactate are associated with increasing levels of anaerobic metabolism. Persistently elevated lactate levels may parallel the degree of malperfusion or organ failure.*  
*High lactate carries adverse prognostic value if elevated to >18 mg/dL (≥2 mmol/L), and still worse outcomes are associated with levels >36 mg/dL (≥4 mmol/L).*  
*Lactate clearance (the rate at which lactate is cleared over a period of 6 hours) has been demonstrated to be as useful as more invasive tests, such as central venous oxygen saturation, in determining a patient’s response to treatment.[77][78] |
| **CRP**                                        | *Baseline test. A marker for inflammation.*                                               |
| **blood culture**                              | *Blood cultures should be taken immediately, and preferably before antibiotics are started, provided their sampling will not delay administration of antibiotics.*  
*Ideally, at least one set should be taken percutaneously, and one set from any vascular access device that has been in situ for more than 24 hours.[64][65] |
| **other cultures (e.g., of sputum, stool, urine, wounds, catheters, prosthetic implants, epidural sites, pleural or peritoneal fluid)** | *Other cultures (e.g., of sputum, stool, and urine) should be taken as clinically indicated.*  
*If meningitis is suspected, a lumbar puncture (LP) for CSF microscopy and culture should be performed. A CT scan prior to performing a LP to exclude raised intracranial pressure is required if there is any clinical suspicion of this.*  
**[VIDEO: Diagnostic lumbar puncture in adults: animated demonstration]**  
*If an enclosed collection such as an abscess or empyema is suspected, it is recommended that this be drained and cultured early in the course of the illness (within 6 hours following identification).[72]  
*Intubated patients in whom there is a suspicion of pneumonia should have tracheal aspirates, bronchoalveolar lavage, or protected brush specimens taken.*  
*If no localizing signs are present, examination and culture of all potential sites of infection, including wounds, catheters, prosthetic implants, epidural sites, and pleural or peritoneal fluid, as indicated by the clinical presentation and history, is required.* |
| **may be elevated; levels >18 mg/dL (≥2 mmol/L) associated with adverse prognosis; even worse prognosis with levels >36 mg/dL (≥4 mmol/L)** |

<tbody>
<tr>
<td><strong>Lumbar puncture</strong></td>
<td>elevated WBC count, presence of organism on microscopy, and positive culture</td>
</tr>
</tbody>
</table>
| • Performed if meningitis suspected, provided no suspicion of raised intracranial pressure. A CT scan is required prior to performing an LP to exclude elevated intracranial pressure if there is any clinical suspicion of this.  
• Bacterial meningitis: WBC count >1000/microliter; protein is elevated; glucose is normal or reduced; cell differential is predominantly neutrophils.  
• Viral meningitis may be associated with lower WBC counts and predominant lymphocytes.  
• **[VIDEO: Diagnostic lumbar puncture in adults: animated demonstration]** | |
| **Echocardiogram (transthoracic or transesophageal)** | inadequate left ventricular filling suggests hypovolemia; vegetations, if endocarditis is cause of sepsis |
| • A transthoracic or transesophageal echocardiogram is useful in patients at risk of, or with symptoms compatible with, bacterial endocarditis.  
• If readily available, may also be appropriate in patients with sepsis of unknown origin.  
• Also helpful to differentiate between hypovolemic, cardiac, and septic shock.  
• May determine alternative diagnoses, such as valvular abnormalities, pulmonary embolus, myocardial ischemia, segmental or global dysfunction, hypovolemia, and pulmonary hypertension. | |
| **Ultrasound scan**                       | may demonstrate abscess, fluid collection, pneumoperitoneum from perforated viscus, obstruction of GI/renal/biliary tracts |
| • Including but not limited to abdominal ultrasound scan.  
• May indicate source of infection (e.g., dilated common bile duct indicating biliary obstruction). | |
| **CT chest or abdomen**                   | abscess, effusion may be demonstrated   |
| • If clinically indicated to establish source of infection.  
• Requires transfer of potentially unstable patients and the benefit should be weighed against the risk. | |
| **Serum procalcitonin**                   | elevated |
| • Where available, measurement of serum procalcitonin should be considered in all patients with sepsis to guide antibiotic therapy. Among patients with acute respiratory infections (including those resulting in sepsis), procalcitonin-guided therapy was associated with a 2 day reduction in the antibiotic course, a 27% reduction in antibiotic related side-effects, and a 10% reduction in 30 day mortality rate. [80]  
• However, evidence for the prognostic value of procalcitonin alone is unclear,[81] and its use in the identification of sepsis is excluded from many guidelines. In addition, changes in procalcitonin levels may occur later than that of lactate, although changes in both markers combined are highly predictive of outcome between 24 and 48 hours.[82] | |

</tbody>
</table>
| **Myocarditis**                 | • Patients typically present with a viral prodrome, dyspnea, or underlying autoimmune condition, such as SLE.  
• Medications such as antibiotics, thiazide diuretics, antiepileptics, digoxin, lithium, amitriptyline, and dobutamine may be suggestive of drug etiology. | • ECG may show nonspecific ST-segment and T-wave abnormalities.  
• Inflammatory markers may be elevated.  
• Two-dimensional echo demonstrates global and regional LV motion abnormalities and dilatation. |
| **Acute pancreatitis**          | • May present with abdominal pain and hypovolemia.  
• There may be a history of gallstones, alcohol use, or viral infections (e.g., mumps). | • Elevated serum amylase, lipase, glucose; low calcium. |
| **Massive pulmonary embolism**  | • Presents with acute dyspnea, pleuritic chest pain, and hypotension. | • CT pulmonary angiogram shows a filling defect in the pulmonary arteries. |
| **Leukemia**                    | • May present with fever, leukocytosis, anemia, tachycardia, multiorgan dysfunction, and dyspnea, and thus meet diagnostic criteria for (suspected) sepsis.  
• The immunocompromise may additionally facilitate development of infections or the increased clinical suspicion of undiagnosed infection. | • Biopsies of blood smear, bone marrow, tumor, or lymph nodes may identify neoplastic cells.  
• Identification of a specific infectious agent is definitive in differentiating sepsis from SIRS. |
| **Malignant hyperthermia**      | • This is a rare condition characterized by severe hyperthermia (>106°F [41.1 °C]) and muscle rigidity following administration of anesthetic agents (e.g., succinylcholine for intubation). Lactic acidosis, hyperkalemia, rhabdomyolysis, hypoxia, and arrhythmias may also occur.[89]  
• Malignant hyperthermia is an inherited disorder (autosomal dominant) and a high index of suspicion is necessary if there is a positive family history.[89] | • The caffeine-halothane contracture test (CHCT) is most commonly used to screen for susceptibility, as ryanodine receptor gene (RYR1) identification is gaining in clinical importance.[90]  
• The CHCT requires muscle biopsy and testing in select regional laboratories after resolution of the episode.  
• Neither test is clinically useful to direct therapy in the acute situation. |
### Condition | Differentiating signs / symptoms | Differentiating tests
--- | --- | ---
Drug-induced fever and coma | • This includes neuroleptic malignant syndrome, serotonergic syndrome, delirium tremens, and metformin lactic acidosis.  
• History of causative drug use. | • Clinical diagnosis. Specific tests are not readily available.

### Diagnostic criteria

There are multiple scoring systems and definitions for sepsis and sepsis with organ dysfunction. None is perfect and many seek to measure similar variables. The systemic inflammatory response syndrome (SIRS) criteria and the 1991/2001 International Consensus definitions of sepsis, severe sepsis, and septic shock remain clinically established in most clinical settings. The Sequential (Sepsis-related) Organ Failure Assessment (SOFA) score is recommended in the 2016 international consensus definitions, and may replace SIRS, but it is important to recognize that the clinical utility of any score relies on individual practitioner clinical assessment and decision-making.

#### Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) (2016)[1]

1. Sepsis: the third international consensus definition published in 2016 redefines sepsis as life-threatening organ dysfunction caused by a dysregulated host response to infection. According to the 2016 consensus definitions, an increase in SOFA score of 2 or more constitutes organ dysfunction. The SOFA score is calculated based on the assessment of the following systems in the ICU setting:

- Respiratory (PaO2/FiO2 ratio)
- Neurological (as assessed by the Glasgow coma scale)
- Cardiovascular (mean arterial pressure [MAP] or administration of vasopressors)
- Coagulation (platelet count)
- Renal (creatinine level and urine output)
- Hepatic (bilirubin level).

The 2016 consensus definitions recommend that the SOFA criteria should replace the previously recommended SIRS criteria. Furthermore, the "quick" (q)SOFA criteria are recommended for use outside of the ICU setting to promptly identify patients with suspected infection who are likely to have a poor outcome. According to the 2016 consensus definitions, patients with 2 or more of the following qSOFA criteria are likely to have poor outcomes typical of sepsis:

- Alteration in mental status
- Systolic blood pressure ≤100 mmHg
- Respiratory rate ≥22 per minute.
2. Severe sepsis: in light of the revisions to the definition of sepsis, the 2016 consensus definitions recommend that the term “severe sepsis” (as defined in the 1991/2001 consensus definitions) should be made redundant.

3. Septic shock: the definition of septic shock has been redefined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone.[1] According to the 2016 consensus definitions, septic shock is defined as sepsis with both:

- Persistent hypotension requiring vasopressors to maintain MAP ≥65 mmHg, and
- Serum lactate level >18 mg/dL (>2 mmol/L) despite adequate volume resuscitation.

**Revised International Consensus Definitions for Sepsis and Septic Shock: SIRS in the presence of infection (2001)**[5]

These criteria have in principle been superseded by the Sepsis-3 definitions. However, they remain in widespread use in clinical practice.

1. Definitive diagnosis requires clinical identification of infection in a patient who also meets the clinical criteria for the SIRS. According to the revised consensus conference definition published in 2001, SIRS is defined by the presence of 2 or more criteria from a collection of clinical signs and laboratory investigations as follows: [Surviving Sepsis Campaign: evaluation for severe sepsis screening tool]

- Temperature >101°F (38.3°C) or <96.8°F (36.0°C)
- Tachycardia >90 bpm
- Tachypnea >20 breaths/minute or PaCO2 <32 mmHg
- Hyperglycemia (blood glucose >140 mg/dL [>7.7 mmol/L]) in the absence of diabetes mellitus
- Acutely altered mental status
- Leukocytosis (WBC count >12,000/microliter)
- Leukopenia (WBC count <4000/microliter)
- Normal WBC count with >10% immature forms.

2. Sepsis: when SIRS is present in an individual patient and the cause is thought to likely be an infection, sepsis is present.

3. Severe sepsis: present when sepsis leads to dysfunction of 1 or more organ systems, and includes the subset septic shock. Organ dysfunction variables are:

- Arterial hypoxemia (PaO2/FiO2 ratio <300) with new pulmonary infiltrates
- A new or increased oxygen requirement to maintain SpO2 >90%
- Acute oliguria (urine output <0.5 mL/kg/hour for at least 2 hours)
- Serum creatinine >2.0 mg/dL
- Coagulation abnormalities (INR >1.5 or aPTT >60 seconds)
- Thrombocytopenia (platelets <100,000/microliter)
- Hyperbilirubinemia (total bilirubin >4 mg/dL)
- Arterial hypotension (systolic BP <90 mmHg, mean BP <65 mmHg, or reduction in systolic BP >40 mmHg from baseline)
- Serum lactate >18 mg/dL (>2 mmol/L).

4. Septic shock is defined as:
Sepsis in adults

• Arterial hypotension (systolic BP <90 mmHg, mean BP <65 mmHg, or reduction in systolic BP >40 mmHg from baseline) persisting for at least 1 hour despite adequate fluid resuscitation, or
• Serum lactate >36 mg/dL (>4 mmol/L) after adequate fluid resuscitation.

The use of vasopressor agents to correct hypotension does not exclude shock.

Sepsis: recognition, diagnosis and early management (National Institute for Health and Care Excellence, 2016)[9]

In the UK, the National Institute for Health and Care Excellence (NICE) has published guidance on the recognition, diagnosis, and early management of sepsis, which includes specific criteria for risk stratification of adults with suspected sepsis. [NICE: risk stratification tool for adults with suspected sepsis]

Acute Physiology and Chronic Health Evaluation II score (APACHE II)[91]

The APACHE score is commonly used to establish illness severity in the ICU and predict the risk of death.

[VIDEO: APACHE II scoring system ]

There is a high risk of death if the score is ≥25.

Other sepsis risk-scoring models

Several other models have been developed for use in the ICU, including APACHE III, the Simplified Acute Physiology Score, and the Mortality Probability Model II.[32] [92] [93]

Patient group-specific scoring systems have also been developed. For example, the Predisposition Insult Response and Organ failure (PIRO) and the Mortality in Emergency Department Sepsis (MEDS) scores have been developed to risk-stratify patients with sepsis or septic shock who are admitted to the emergency department;[94] the Sepsis in Obstetrics Score (SOS) has been developed to risk-stratify pregnant or postpartum women with sepsis.[95] These scoring systems can assist in the identification and management of sepsis in specific patient groups.[96]

There are numerous ongoing studies investigating techniques for “staging” the severity of sepsis using a variety of blood-borne markers.[81] [97] Although some techniques have shown initial promise, the evidence base remains weak, and they have an unclear role in future clinical practice.
Step-by-step treatment approach

Early recognition and treatment of sepsis is key to improving outcomes. Treatment guidelines have been produced by the Surviving Sepsis Campaign, and remain the most widely accepted standards. Current best practice is based upon evidence for care bundles in sepsis. They include:

- Obtain blood cultures prior to administration of antibiotics
- Administer broad-spectrum antibiotics that target the suspected pathogen(s)
- Administer 30 mL/kg crystalloid for hypotension or lactate ≥36 mg/dL (≥4 mmol/L)
- Obtain serial measurement of blood lactate
- Use vasopressors to maintain a mean arterial pressure (MAP) ≥65 mmHg in patients refractory to fluid therapy
- In patients with an initial lactate ≥36 mg/dL (≥4 mmol/L), or who are persistently hypotensive (i.e., MAP <65 mmHg), assess volume status and perfusion using either a repeat focused exam (including vital signs and cardiopulmonary, capillary refill, pulse, and skin findings), or 2 of the following methods:
  - Measurement of central venous pressure (CVP)
  - Measurement of central venous oxygen saturation (ScvO2)
  - Bedside cardiovascular ultrasound
  - Dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge.

In the UK, the National Institute for Health and Care Excellence (NICE) guidelines recommend administering crystalloid if the patient has a lactate ≥18 mg/dL (≥2 mmol/L) and at least one high risk criterion. Crystalloids are also recommended if the patient has a lactate >18 mg/dL (>2 mmol/L) and at least two moderate to high risk criteria, or evidence of acute kidney injury. Crystalloid can be considered in patients with a lactate <18 mg/dL (<2 mmol/L) if they have at least one high risk criterion.

The Sepsis Six

One bundle dealing with basic therapies, the "Sepsis Six", has been shown to improve outcomes in septic patients. If the 6 factors are completed within the first hour following recognition of sepsis, the associated mortality has been reported to reduce by as much as 50%. The 6 factors are as follows:

- Administer high-flow oxygen to maintain target oxygen saturations greater than 94% (or 88%-92% in people at risk of hypercapnic respiratory failure)
- Take blood cultures
- Give intravenous antibiotics
- Start intravenous fluid resuscitation
- Check lactate level
- Monitor hourly urine output.

Patients who are refractory to initial treatments, in particular those with septic shock, may require invasive monitoring and consideration for organ support (e.g., central venous catheter and vasopressors), so management on a high dependency unit or ICU may well be required.

One aspect of basic intervention, the delivery of appropriate rapid fluid challenges, is intended to restore the imbalance between oxygen supply and demand to the tissues. Patients who fail to respond to the rapid delivery of adequate volumes of intravenous fluids are in septic shock. The immediate priority in this group of patients is the restoration of the circulation and oxygen delivery.
Early goal-directed fluid therapy has previously been the gold standard of care,[6] [56] [59] [86] [88] [100] [101] but several randomized, prospective studies have found no discernible benefit with this therapy over usual care.[102] [103] [104] [105] [106] However, the central tenets of early goal-directed therapy (e.g., restoration of circulating volume, correction of hypotension, and assessing cardiac output) remain important to the management of sepsis and have now become standard practice in many emergency departments.

Monitoring of vital signs and response to fluid therapy is essential. Assessment of oxygenation via pulse oximetry and serial lactate measurements should be performed, along with monitoring of urinary output. A failure of lactate to improve with therapy is indicative of a poor outcome. Lactate clearance has been shown to correlate positively with survival.[77] All patients receiving vasopressors should have an arterial catheter inserted as soon as it is practical to do so to aid more accurate monitoring of arterial blood pressure.[88]

**Antibiotic therapy**

Broad-spectrum intravenous antibiotics should be given before a pathogen is identified.[88] [107] [108] They are recommended within the first hour once sepsis is diagnosed, preferably after cultures have been taken.[88] [9] The delivery of appropriate antibiotics within the first hour is of critical importance in maximizing chances of survival.[60] [109] [110] [111]

Knowledge of locally prevalent pathogens and their antibiotic resistance patterns are important when deciding empiric therapy.[12] [107] Empirical antibiotic recommendations will be necessarily individualized at the institutional level, based on local antibiotic protocols. Once culture and sensitivity results are available, antibiotics can be tailored to the known pathogens. Cultures should be repeated (e.g., at 6-hour to 8-hour intervals) if there are persistent or repeated fever spikes, or there is the identification of a new site of infection. Antibiotics should be given targeted to the presumed site of infection. If there is no clinical evidence to suggest a site of infection, empiric broad-spectrum antibiotics should still be given.

Empirical antibiotics should be narrowed as soon as a pathogen has been identified and sensitivities are available.[88]

**Respiratory source**

Respiratory infections account for approximately 30% to 50% of cases. Monotherapy appears as effective as combination therapy in community-acquired pneumonia, although some units prefer combination therapy in patients with severe pneumonia requiring critical care admission.[112] Treatment regimens should cover common respiratory pathogens and atypical organisms such as *Legionella pneumophilia*.

Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. Combination therapy should include a beta-lactam, such as penicillin G, cefotaxime, or ampicillin/sulbactam, with a macrolide such as azithromycin. A suitable monotherapy treatment regimen is to use a respiratory quinolone, such as moxifloxacin or levofloxacin, or alternatively, doxycycline. These monotherapy regimens are suitable for patients with penicillin allergy.

Risk factors for the presence of multiple-drug-resistant pathogens (MDRPs) for *Pseudomonas aeruginosa* and for methicillin-resistant *Staphylococcus aureus* (MRSA) will affect choice of antimicrobial agents and should be evaluated. These include hospitalization (for >48 hours, including residence in nursing home) or systemic antibiotic use within the previous 90 days. A history of MRSA
Sepsis in adults

**Treatment**

Infection or colonization should be sought. Recently, increasing numbers of cases of community-acquired MRSA pneumonia have been reported, particularly in association with influenza virus infection. Mortality rates appear somewhat higher than for non-MRSA severe pneumonia at 33%.[113]

MRSA should be considered in patients presenting with particularly severe community-acquired pneumonia, especially in the presence of hemoptysis, shock, and an influenza-like prodromal illness.[114][115][116]

In high-risk patients, a broader spectrum of cover can be achieved using a carbapenem such as imipenem/cilastatin, or an antipseudomonal penicillin (such as piperacillin/tazobactam) in combination with an aminoglycoside (such as gentamicin). Tigecycline is an alternative for patients with penicillin allergy; however, monotherapy with this drug should be used with caution as it may be associated with an increased risk of mortality. Expert advice should be sought before using tigecycline.[117] In patients at risk of MRSA, or with unusual severity of pneumonia with hemoptysis, vancomycin or linezolid should be added to one of the above regimens. In patients with significant risk factors for *Pseudomonas* infection (bronchiectasis, systemic corticosteroid use, malnourishment), consideration should be given to the addition of ciprofloxacin to one of the above regimens.

**Urinary tract source**

Urinary tract infections account for approximately 10% to 20% of cases. Ensuring patency of the urinary tract is vital. Cover should include gram-negative coliforms and *Pseudomonas*. Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. A suitable treatment regimen is to use a combination of either ampicillin or a cephalosporin, such as cefotaxime with gentamicin. Ciprofloxacin is a suitable alternative in patients with penicillin allergy.

**Abdominal source**

Infection arising from abdominal sources accounts for approximately 20% to 25% of cases. Gram-positive and gram-negative organisms including anaerobes should be covered. Peritonitis or intra-peritoneal abscesses require urgent surgical drainage or (where appropriate) percutaneous drainage.

Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. Treatment with ampicillin or cefotaxime with metronidazole and gentamicin is a suitable regimen, or alternatively, piperacillin/tazobactam with gentamicin. A regimen of tigecycline and gentamicin is a suitable choice in patients with penicillin allergy.

Patients with recurrent perforation of the large intestine are at increased risk of invasive fungemia. An azole, such as fluconazole, or an echinocandin, such as micafungin, should be added to the antibacterial cover. Non-albicans species of *Candida* are increasingly resistant to azoles.[40][41][118]

**Soft-tissue and joint source**

This heterogeneous group of infections includes septic arthritis, wound infections, cellulitis, and acute super-infections arising from chronic ulceration, and accounts for approximately 5% to 10% of cases. A high index of suspicion should also be held for necrotizing fasciitis, which requires immediate surgical intervention (as does septic arthritis). Most infections are polymicrobial, and broad-spectrum cover against gram-positive and gram-negative organisms including anaerobes should be used.
Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. A suitable regimen is to use nafcillin (or tigecycline in penicillin-allergic patients) together with metronidazole. Alternatively, clindamycin may be used. If the patient has risk factors for MRSA, vancomycin (or alternatively linezolid) should be added.

If necrotizing fasciitis is suspected, clindamycin together with nafcillin or tigecycline would be a sensible choice.

**CNS source**

CNS infections are a relatively uncommon but potentially devastating cause of sepsis, accounting for under 5% of cases. Meningococcal septicemia can be extremely rapidly fatal, and if survived, can lead to greater morbidity than other forms. Immediate antibiotic therapy in suspected cases is essential.

Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. Suspected meningitis or meningococcal septicemia should be treated immediately using a third-generation cephalosporin, such as ceftriaxone or cefotaxime. For patients with penicillin allergy, vancomycin with chloramphenicol is a suitable alternative. Some suggest the addition of rifampin to either regimen to aid penetration.

For patients over 50 years, and those with a history of alcoholism or other debilitating illness, or at increased risk of infection with *Listeria*, cephalosporins alone provide inadequate cover. Ampicillin should be added to the regimen, provided the patient is not allergic to penicillin. For those allergic to penicillin, erythromycin or trimethoprim/sulfamethoxazole can be substituted.

Patients with a more insidious onset of CNS symptoms should be suspected as having viral encephalitis. Viruses cause sepsis extremely rarely, but early use of antiviral agents such as acyclovir may improve outcome.

Corticosteroids for bacterial meningitis can improve neurologic outcomes.[119]

**Sepsis of unknown origin**

Intensive efforts, including imaging, should be undertaken to attempt to evaluate the source of infection. Urgent broad-spectrum coverage to include all common pathogens should be administered.

Antibiotics listed are suggested as guidance only. Local or national policy, which may take into account specialist knowledge of sensitivity patterns, should be sought and adhered to when possible. Carbapenems give appropriately broad cover; with imipenem or meropenem being suitable choices. Piperacillin/tazobactam with gentamicin is an alternative. If the patient has risk factors for MRSA, vancomycin should be added.

**Fluid resuscitation**

Early, vigorous fluid resuscitation in sepsis-induced hypoperfusion is needed with at least 30 mL/kg body weight of crystalloid given within the first 3 hours.[88] Additional fluid may be required, but this should be guided by thorough clinical assessment of the patient's hemodynamic status.[88]

Repeated fluid boluses of crystalloid (typical volume 500 mL) given over 5 to 30 minutes may be effective in correcting hypotension secondary to hypovolemia. Boluses of a colloid solution (typical volume
250-300 mL) may be used as an alternative, but no evidence supports the use of colloids over other fluids such as crystalloids or albumin solution.[120] [121] [122] [123] [124] [125] [126] [127] [128] Solutions containing starch may be harmful and should be avoided.[88] Evidence has shown that solutions containing hydroxyethyl starch (HES) are associated with a greater risk of renal dysfunction and adverse outcome.[129] [130] [131] [132] [133] [134] [135] HES solutions for infusion have been suspended from the market across the European Union owing to patient safety concerns related to the increased risk of kidney injury and death in certain patient groups, including critically ill patients and those with sepsis. The market suspension followed a January 2018 review by the European Medicines Agency's Pharmacovigilance Risk Assessment Committee that found HES solutions were still being used in these patient groups despite restrictions introduced in 2013. [136]

Normal saline and albumin should be given according to local protocols. Current evidence suggests that resuscitation using albumin-containing solutions is safe, but evidence of its efficacy is insufficient to recommend its use over crystalloids.[128] [137] [138] Red cell or plasma transfusion may be considered to target specific deficiencies but should not be used for volume augmentation. Aggressive red cell transfusion has not been shown to improve outcomes.[139]

Patients should be monitored closely for signs of fluid overload (e.g., pulmonary or systemic edema).[140] Changes in inferior vena cava (IVC) diameter during respiration (visualized using bedside ultrasound) have been shown to be an accurate means of judging fluid responsiveness, and requirement for further intravenous fluids. In the spontaneously breathing patient, a collapsed or collapsing IVC suggest that cardiac output will improve with additional fluid resuscitation. In the mechanically ventilated patient, an increase in IVC size >18% (or visible to the naked eye) with positive pressure ventilation, fluid responsiveness is expected.[141] [142] One systematic review has shown passive leg raising to be an accurate predictor of fluid responsiveness in ventilated patients, regardless of ventilator mode or technique, and with flow variables (e.g., cardiac output) having greater accuracy compared with pulse pressure.[143]

**Glycemic control in the critically ill**

There has been a shift of opinion and practice regarding glycemic control in the critically ill. Since 2001, the use of tight glycemic control in septic patients has been advocated. However, more recent evidence suggests an increase in adverse events (e.g., severe hypoglycemia) in patients managed with tight glycemic control (target blood glucose 110 mg/dL).[131] [144] An international randomized controlled trial demonstrated an increase in the absolute risk of death at 90 days by 2.6 percentage points in the patient group managed with intensive glycemic control compared with the group managed with conventional glycemic control (blood glucose target of 180 mg/dL).[145] The American Diabetes Association recommends a general glucose goal of 140 to 180 mg/dL in critically ill diabetic patients, preferably with use of an insulin infusion protocol.[146] The Surviving Sepsis Campaign recommends the use of validated insulin infusion protocols targeting a blood glucose level of <180 mg/dL.[88]

**Persistent hemodynamic instability**

If hypotension persists, with a MAP of <65 mmHg, a vasopressor should be started.[88] [147] Norepinephrine administered via a central venous catheter is the drug of choice as it increases MAP. Vasopressin or epinephrine can be added to norepinephrine to achieve the target MAP (≥65 mmHg), or vasopressin can be added to wean norepinephrine.[88] Dopamine is an option, but should only be given to highly selected patients as it has been associated with higher mortality than norepinephrine.[88] [148] [149] All infusions of vasoactive medications to correct shock should be given via a secure catheter in a
central vein with high flow, such as via a central venous catheter, unless resources do not permit this and the situation is urgent. The use of low-dose dopamine for renal protection is not recommended.[88]

**Adjunctive therapies**

In patients with low cardiac output despite adequate fluid resuscitation, inotropes (e.g., dobutamine) can be added. Low cardiac output suspected through clinical exam (prolonged capillary refill times, low urine output, poor peripheral perfusion) can be confirmed through the use of cardiac output monitoring or by sampling central venous or pulmonary arterial blood to measure oxygen saturations. Heart rate should be kept <100 bpm to minimize myocardial oxygen demand.[147]

Current guidelines recommend that low-dose corticosteroids are given only to patients whose BP is poorly responsive to both fluid resuscitation and vasopressor therapy.[88] However, evidence for giving corticosteroids to patients with sepsis or septic shock is mixed.[150] [151] [152] [153] [154] [155] [156] In a large randomized controlled trial published in January 2018, patients with septic shock who received infusions of hydrocortisone had no significant improvement in 28-day or 90-day mortality rates compared with those who received placebo (90-day mortality of 27.9% in the hydrocortisone group vs 28.8% for placebo). Those who received hydrocortisone did experience faster resolution of shock (median 3 vs 4 days) and were less likely to need a blood transfusion (37.0% vs 41.7%) but there were no significant differences in length of ICU stay or need for renal replacement therapy. [157]

Other more novel therapies include bathing patients with chlorhexidine washes, which may decrease the rate of hospital-acquired infections,[158] and antioxidants such as N-acetylcysteine. These agents have been used as an adjuvant therapy in sepsis with the aim of decreasing the levels of reactive oxygen species. However, they have been found to be ineffective and their use is not currently recommended.[159]

**Standard ICU supportive care**

All patients with sepsis should be considered for admission to the high dependency unit or ICU.[56] [140]

General intensive care measures include stress ulcer prophylaxis with histamine H2 receptor antagonists or proton pump inhibitors (in patients at risk of GI bleeding), DVT prophylaxis (with heparin and compression stockings), enteral or parenteral nutrition, and glycemic control.[88] [100] [160]

Transfusion of packed cells may be required. Despite studies of early goal-directed therapy transfusing to a target hemoglobin concentration of >10 g/dL, it is recommended that a lower threshold of 7 g/dL be used.[88] Reasons for this include resource usage and a number of studies in the general critical care population showing no improvement with a higher hemoglobin threshold compared with a lower hemoglobin threshold,[139] and potential harm associated with liberal transfusion.[161] A higher hemoglobin level may be necessary in certain circumstances (myocardial ischemia, severe hypoxemia, acute hemorrhage, cyanotic heart disease, or lactic acidosis).[88] In the initial resuscitative phase, particularly with the application of early goal-directed therapy, a higher hematocrit of ≥30% may be appropriate.[56]

Patients requiring prolonged ventilatory support should receive lung-protective ventilation using minimal peak inspiratory pressures (<30 cmH2O) and permissive hypercapnia to specifically limit pulmonary compromise.[162] FiO2 should be titrated to lowest effective levels to prevent oxygen toxicity and maintain central venous oxygen tension. Patients should be placed in a semirecumbent position with the head elevated to 30° to 45°.[88]

### Treatment

mg/dL (>2 mmol/L) and at least two moderate to high risk criteria, or evidence of acute kidney injury. Crystalloid can be considered in patients with a lactate <18 mg/dL (<2 mmol/L) if they have least one high risk criterion.

- Solutions containing starch may be harmful and should be avoided. Evidence has shown that solutions containing hydroxyethyl starch (HES) are associated with a greater risk of renal dysfunction and adverse outcome.

- Red cell or plasma transfusion may be considered to target specific deficiencies but should not be used for volume augmentation. Aggressive red cell transfusion has not been shown to improve outcomes.

- Normal saline and albumin should be given according to local protocols. Current evidence suggests that resuscitation using albumin-containing solutions is safe, but evidence of its efficacy is insufficient to recommend its use over crystalloids.

- Patients should be monitored closely for signs of fluid overload (e.g., pulmonary or systemic edema).

### adjunct standard supportive ICU care

- All patients with sepsis should be considered for admission to the high dependency unit or ICU.

- General intensive care measures include stress ulcer prophylaxis with histamine H2 receptor antagonists or proton pump inhibitors (in patients at risk of GI bleeding), DVT prophylaxis (with heparin and compression stockings), enteral or parenteral nutrition, and glycemic control. The American Diabetes Association recommends a general glucose goal of 140 to 180 mg/dL in critically ill patients and those with sepsis.

  - **meropenem**: 1 g intravenously every 8 hours
Recommendations

**Monitoring**

Standard monitoring of vital signs, pulse oximetry, ECG, regular laboratory tests, and urinary output by catheterization are routinely performed. All patients receiving vasopressors should have an arterial catheter inserted as soon as it is practical to do so, to aid more accurate monitoring of arterial blood pressure.[88]

Patients with evidence of circulatory dysfunction or shock should be managed in a critical care or higher dependency area. Central venous catheters will be required to ensure reliable delivery of vasoactive medication. The principles of Early Goal-Directed Therapy[56] remain relevant in ongoing care for patients with shock.

Central venous pressure (CVP) may be used in combination with clinical assessment and other monitoring modalities to guide ongoing fluid resuscitation. Additional monitoring techniques include the use of stroke volume variability (an index of change in stroke volume with each contraction), cardiac ejection time (corrected for heart rate) and changes in inferior vena cava (IVC) diameter during respiration (visualized using bedside ultrasound).[141] [142] Mechanical ventilation can alter cardiac filling pressures and affect measurement. CVP values must be corrected with increasing levels of positive end-expiratory pressure (PEEP) or hemodynamic parameters.[56] [188] In the spontaneously breathing patient, a collapsed or collapsing IVC suggest that cardiac output will improve with additional fluid resuscitation. In the mechanically ventilated patient, if IVC size increases by >18% (or visible to the naked eye) with positive pressure ventilation, fluid responsiveness is expected. One systematic review has shown passive leg raising to be an accurate predictor of fluid responsiveness in ventilated patients, regardless of ventilator mode or technique, and with flow variables (e.g., cardiac output) having greater accuracy compared with pulse pressure.[143]

Central venous catheters may also be used to sample central venous oxygen saturation (ScvO2), which gives a global indication of the balance between tissue oxygen demand and supply. If ScvO2 is low (<70%), it is likely that oxygen delivery is inadequate and the need for blood transfusion (to increase oxygen carrying capacity) or inotropes (to increase cardiac output) should be assessed. Other measures of the adequacy of oxygen delivery are increasingly used, including the use of lactate clearance rate over the first 6 hours. Lactate clearance has been shown to correlate positively with survival.[77]

The use of pulmonary artery catheters may be an advantage in selected patients with suspected cardiac compromise or complicated presentations. It is not considered to be essential as a first-line routine monitor, and its use in clinical practice has been largely superseded by less invasive cardiac output monitoring modalities, including esophageal Doppler, arterial pulse contour analysis, and thermodilution/indicator dilution techniques.

Complications

<table>
<thead>
<tr>
<th>Complications</th>
<th>Timeframe</th>
<th>Likelihood</th>
</tr>
</thead>
<tbody>
<tr>
<td>renal dysfunction</td>
<td>short term</td>
<td>high</td>
</tr>
</tbody>
</table>

Transient oliguria is common and is related to hypotension. Rarely, anuria occurs.[182] Acute kidney injury is relatively common but is rarely associated with histologic change or with any need for long-term renal replacement therapy.

Correction of volume depletion and hypotension generally reverses oliguria.[182]
Sepsis in adults

Follow up

<table>
<thead>
<tr>
<th>Complications</th>
<th>Timeframe</th>
<th>Likelihood</th>
</tr>
</thead>
<tbody>
<tr>
<td>hypotension</td>
<td>short term</td>
<td>high</td>
</tr>
</tbody>
</table>

Volume depletion is caused by reduced oral intake, increased venous capacitance, increased fluid losses due to pyrexia, capillary leakage leading to edema, tachypnea, diarrhea, and possibly bleeding. Persistent hypotension is often due to a combination of low systemic vascular resistance, hypovolemia and reductions in cardiac output from myocardial failure, excessive PEEP, or acidosis.

Fluid resuscitation is given with either colloids or crystalloids, and early central venous pressure (CVP) monitoring is indicated if rapid response is not achieved. Vasopressors can be started for persistent hypotension or inotropes for myocardial failure. Caution is required to prevent tachyarrhythmia.

<table>
<thead>
<tr>
<th>ARDS</th>
<th>short term</th>
<th>medium</th>
</tr>
</thead>
</table>

Respiratory failure often progresses quickly and is indicated by a respiratory rate >30/minute, even though arterial oxygen levels may be normal.

ARDS may resolve completely or can progress to fibrosing alveolitis with persistent hypoxemia.[181]

Intubation and ventilation reduce respiratory muscle oxygen demand and the risk of aspiration and cerebral anoxia.[182] Lung protective ventilation (low tidal volumes) should be used:[4] Tidal volumes should be reduced over 1 to 2 hours to a target of 6 mL/kg of predicted body weight. Minimum positive end-expiratory pressure (PEEP) is recommended to prevent lung collapse at end expiration.[88]

<table>
<thead>
<tr>
<th>myocardial dysfunction and failure</th>
<th>short term</th>
<th>medium</th>
</tr>
</thead>
</table>

Myocardial dysfunction with biventricular dilatation is a recognized complication of sepsis, but is usually transient and not commonly severe. Death from myocardial failure is rare.[140] Circulating myocardial depressant factors are thought responsible.

After adequate filling pressures have been achieved, inotropic agents should be considered to maintain an adequate cardiac index, mean arterial pressure (MAP), mixed venous oxygen saturation, and urine output.

Clinicians should define specific goals and desired endpoints of inotropic therapy in patients with sepsis and titrate therapy to those end points. These end points should be refined at frequent intervals as patient's clinical status changes.[140]

<table>
<thead>
<tr>
<th>multiple organ system failure</th>
<th>short term</th>
<th>medium</th>
</tr>
</thead>
</table>

The inflammatory response in sepsis causes widespread tissue injury. Multiorgan dysfunction may be partly caused by apoptosis of immune, epithelial, and endothelial cells and a shift to an anti-inflammatory phenotype, compounded by impaired organ perfusion due to hypotension, low cardiac output states, circulatory microthrombi, a disordered microcirculation, and tissue edema.[4]

Failure of each additional organ increases the average risk of death by 15% to 20%. Lung dysfunction tends to occur early and persists. Serious CNS dysfunction or liver function often occur hours to days after sepsis onset and persists for variable periods of time. Most organ failures resolve within a month in surviving patients.[182]

Treatment of multiorgan failure in sepsis is primarily supportive. It includes effective antibiotic therapy, goal-directed therapy (to reverse hypotension, anemia, coagulopathy, bleeding, and shock) and standard supportive ICU care. This may include dialysis, ventilatory support, and sedation.

Prognosis

The prognosis in patients with sepsis and septic shock is guarded at best. The mortality rate from sepsis has been estimated in a number of studies to be between 28\% and 50\%.\[178\] [179] More recently, the SOAP
Sepsis in adults

Follow up

study in Europe observed an overall hospital mortality of 36%,[34] and the Surviving Sepsis Campaign reported mortality by the end of an improvement project to be 31%.[10]

ICU-specific mortality has been shown to be 27% to 32% in patients with sepsis, and 50% to 70% in patients with septic shock, compared with 14% in ICU patients without sepsis.[4] [12]

Multiorgan compromise is common in advanced sepsis with variable residual morbidity.[4] [8]

United Kingdom Sepsis Trust, Chief Executive, Global Sepsis Alliance, Programme Director, Survive Sepsis, Consultant in Critical Care and Anaesthesia, Heart of England NHS Foundation Trust, Birmingham, UK

DISCLOSURES: RD has received payment for consultancy on sepsis from Kimal Plc, manufacturers of vascular access devices, from the Northumbria Partnership, a patient safety collaborative, and, where annual leave or other income was compromised in fulfilling his charity duties, from the UK Sepsis Trust. RD has received sponsorship to attend and speak at one meeting from Abbott Diagnostics. He is CEO of the UK Sepsis Trust and Global Sepsis Alliance, and advises HM Government, the World Health Organisation and NHS England on sepsis. Each of these positions demands that he express opinion on strategies around the recognition and management of sepsis.
